Optimal Location and Size of Distributed Generation to Reduce Power Losses based on Differential Evolution Technique

Noor Izzri Abdul Wahab, Ahmed Sahib Hammadi and Mohammad Lutfi Othman

Department of Electrical and Electronic Engineering, Faculty of Engineering, Universiti Putra Malaysia, 43400 UPM, Serdang, Selangor, Malaysia

ABSTRACT

An electric power system generate electricity to meet demands. Distributed Generation (DG) allows electricity to be generated in a small capacity where the customer is located. In this paper, multi-objective functions based on the indices of system performance are formulated and used to determine the best location. The Differential Evolution technique (DE) has been employed to calculate optimal sizing for each location. Unity power factor DG model have been studied in this work and the problems solved with one DG unit. IEEE 14 bus has been used as a test system.

Keywords: Distributed Generation (DG), Differential Evolution (DE), multi-objective function (MOF)

INTRODUCTION

Major changes in technology, environmental policies and expansion of power markets have enabled the distribution of electricity in a small capacity to power networks (Karimyan, Gharehpetian, Abedi, & Gavili, 2014). The new technology utilises both unconventional and conventional sources of energy. Often, it may be operated by the utility company or the customer. The operation of a DG unit may be considered random depending on customer load (Aman, Jasmon, Bakar, & Mokhlis, 2012). The location and amount of power delivered from DG (Distributed Generation) units into the distribution system can either increase or decrease the efficiency and stability of the system. Therefore, it’s very important to determine the optimal location and size of the DG units before they are inaugurated into the system. In the recent years, numerical calculation approach based on artificial intelligence techniques has been introduced to optimise the operations of the DG. These methods though efficient, are complex and sometimes reproduction of their results may be difficult or impossible. Earlier
studies have examined optimal placement and sizing and evaluation of impact of the DG unit. Adaptive genetic algorithm (GA) was used to reduce power losses and improve the voltage profile under uncertainties load in (Ganguly & Samajpati, 2015). The PSO method was used to find the best location and to determine the optimal size of DG units for improving voltage stability and reducing power losses (Khanjanzadeh, Arabi, Sedighizadeh, & Rezazadeh, 2011). The PSO method was more accurate than the GA method and the speed of convergence was also fast. Firefly Algorithm (FA) method has been employed to determine optimal location and sizing of DG units in the distribution power networks to minimise the total real power loss of system (Sulaiman, Mustafa, Azmi, Aliman, & Rahim, 2012). The Differential Evolutionary (DE) methodology was proposed to achieve optimal location, size and number of capacitor bank in the distribution networks (Karimi, Shayeghi, Banki, Farhadi, & Ghadimi, 2012). The DE method proved effective in in finding the optimal size, location, and number of capacitor banks in terms of speed and accuracy of the results.

In this paper, DE optimisation technique is used to determine the best location and the optimal size of DG unit to reduce power losses and improve the voltage profile of the distribution system.

This paper is organised as follows: The five performance indices relating to DG allocation are discussed in section II. The multi objective functions with corresponding weights are discussed in section -III while optimal sizing and siting of DG unit by using Differential Evolutionary method (DE) is discussed in section IV. In section V, IEEE 14 bus distribution system, methodology and results of the study are discussed. Section VI concludes the paper.

**OBJECTIVE FUNCTION FORMULATION**

Indices show the range of system reliability and in this paper, five indices are used to determine the multi-objective function by giving weight to each index.

1. **Real and Reactive Power Loss Index:** The real and reactive power loss indices are defined as flowing (Ochoa, Padilha-Feltrin, & Harrison, 2006):

   \[ LIP = \frac{P_{\text{loss}}^{\text{with DG}}}{P_{\text{loss}}^{\text{without DG}}} \]  
   \[ LIQ = \frac{Q_{\text{loss}}^{\text{with DG}}}{Q_{\text{loss}}^{\text{without DG}}} \]  

   where; \( P_{\text{loss}}^{\text{with DG}} \) and \( Q_{\text{loss}}^{\text{with DG}} \) and \( P_{\text{loss}}^{\text{without DG}} \) and \( Q_{\text{loss}}^{\text{without DG}} \) are the total real and reactive power losses after and before inclusion of DG units in the distribution system.
2. **Voltage Deviations Index**: One of the advantages of proper location and size of the DG is the improvement in the system voltage profiles. The voltage deviation index can be defined as:

\[
VDI_i = \max_{i \in \mathbb{Z}} \left[ \frac{V_{ref} - V_i}{V_{ref}} \right]
\]

where, \(V_{ref}\) is the voltage of the reference bus (slack bus) and \(n\) is the number of the buses.

3. **Line Loading Index**: The line flows show an increase or decrease at few existing distribution lines when the DG units are placed in the distribution system. The line loading index definition is from: (Seifinajmi & Sakhavat Saghi, 2014)

\[
LLI_i = \max \left( \frac{S_j^{DG}}{S_j^0} \right)^{nl}
\]

where, \(S_j^{DG}\) and \(S_j^0\) are the power flows at the branch \(j\) with and without DG. \(nl\) is the number of the branches.

4. **Short Circuit Index**: This index is related to the protection and selectivity issues where it evaluates the maximum short-circuit current variation of the system in two scenarios, with and without DG (El-Zonkoly, 2011).

\[
SCI_i = \max \left( \frac{I_{SC_i}^{DG}}{I_{SC_i}^0} \right)^{nb}
\]

where, \(I_{SC_i}^{DG}\) and \(I_{SC_i}^0\) are the symmetrical fault current contributions at node \(i\) with and without DG.

The indices proposed in this paper are subject to the following quality and inequality operational constraints:

**Voltage limits**: The voltage drop limits depend on the voltage regulator limits provided by the disco (Kumaraswamy, Tarakalyani, & Prasanth, 2014).

\[
V_{min} \leq V_i \leq V_{max}
\]

**Line Thermal limits**: Power flow through any distribution feeder must comply with the line thermal capacity.

\[
S_i \leq S_{l,\text{max}}
\]
DG capacity: This section defines the boundary of power generator by DG:

\[
P_{\text{DG min}} \leq P_{\text{DG}} \leq P_{\text{DG max}}
\]  

(8)

**MULTI OBJECTIVE FUNCTION FORMULATION**

By calculating the five indices described in the previous section and taking corresponding weights for each index, the Multi-objective Function can be expressed as in equation 9 (Mancer, Mahdad, & Srairi, 2012).

\[
MOP = w_1 LP + w_2 LIQ + w_3 VDI + w_4 LLI + w_5 SCI
\]  

(9)

The sum of the absolute values of the weights assigned to all indices should add up to one as shown in the following equation:

\[
w_1 + w_2 + w_3 + w_4 + w_5 = 1
\]  

(10)

The weight values vary according to concerns of engineers and the importance of electrical standards. Additionally, the weight values are specified to give importance to each index depending on the system. The index that outperforms the others in terms of benefits and importance is given a larger weight.

**DE METHOD FOR OPTIMAL DG ALLOCATION**

The DE technique is one of the evolutionary computation methods which depends on stochastic real parameter algorithms. It is used to solve nonlinear, non-differentiable and multimodal objective functions (Kenneth, 1999). The DE is uses a less stochastic approach and a greedy selection compared with other classical EAs to solve optimisation problems. The basic steps of the standard DE algorithm are described as follows:

*Step 1: Initialisation.* The first operation of the DE algorithm is randomly initiated population (NP) of D-dimensional parameter vectors. These vectors represent a candidate solution to solve the optimisation problem. The initial population can be expressed as:

\[
X_i^0 = [X_1^0, X_2^0, \ldots, X_N^0], (i = 1, 2, \ldots, N_p)
\]  

(11)

\[
X_i^0 = X_{\text{lower}} + (X_{\text{upper}} - X_{\text{lower}})R_i
\]  

(12)

where, \((X_i^0)\) is a D-dimensional vector, and \(R_i = [rm_{i,1}, rm_{i,2}, \ldots, rm_{i,D}]\).
Step 2: Mutation. Three distinct parameter vectors are sampled randomly from the current population to create donor vectors; these indices are generated once for each mutant operator. The scale of difference between two vectors is added to the third one. The mutation strategy is expressed as:

\[ V_I^g = X_{best}^g + F(X_{r1}^g - X_{r2}^g) \]  

where, \( X_{r1}^g \), \( X_{r2}^g \) are the randomly selected vectors among the population, \( X_{best}^g \) is the vector with the best fitness value among the individuals, \( F \) is a scaling factor.

Step 3: Crossover. In crossover operations, the donor vectors \( V^{r} \) reciprocate with the target vectors \( X^{r} \) to create the trial vectors \( U^{r} \). The trial vectors \( u_{ij}^{g} \) can be formulated as:

\[ u_{ij}^{g} = \begin{cases} v_{ij}^{g} & \text{if } (r m_{ij}^{g} \leq CR) \text{ or } j = r m_{ij}^{g} \\ v_{ij}^{g} & \text{if } (r m_{ij}^{g} > CR) \text{ and } j \neq r m_{ij}^{g} \end{cases} \]  

where, \( u_{ij}^{g} \) is a component of \( U_{i}^{g} = u_{i1}^{g}, u_{i2}^{g}, \ldots, u_{iD}^{g} \)

Step 4: Selection. After the crossover process, the generated trial vector may be chosen to be a member of the next generation based on the selection criteria, which is given by:

\[ X_{i}^{g+1} = \begin{cases} U_{i}^{g} & \text{if } \text{fitness}(U_{i}^{g}) < \text{fitness}(X_{i}^{g}) \\ X_{i}^{g} & \text{otherwise} \end{cases} \]  

RESULTS AND DISCUSSIONS

Test System

The DG unit was assumed to be integrated in an IEEE 14 bus test system. Figure 2 shows the single line diagram of IEEE 14-bus test system which consists of 5 generator buses, 9 load buses and 20 branches. The total real load of the system is 259 MW and reactive load is 112 MVar. The real and reactive power losses in the base case of IEEE 14 bus test system obtained using Newton Raphson method is 13.5929 MW and 56.9096 MVar respectively (Pai, 1979).

Figure 1. Single line diagram of IEEE 14 test system
Weights Values

The values of weights in multi-objective function are different based on the engineer’s concern. In general, it is not easy to identify suitable weight values for each index. Engineers and operators of plants who have experience with distribution systems should be able to identify the suitable values of the weights. During this study, the values of the weights were assumed positive and W1 related to active power losses is restricted between 0.35 and 0.50, W2 related to reactive power losses is restricted between 0.1 and 0.30 W3 related to voltage division is restricted between 0.1 and 0.30, W4 and W5 related to capacity of line and short circuit level are fixed at 0.10 (see Table 1).

From Table 1, set number 4 which shows the minimum fitness function is selected as a weighting set for MOF eq. (9). Thus, the weights for each index are described as $w_1=0.35$, $w_2=0.15$, $w_3=0.30$, $w_4=0.10$ and $w_5=0.10$.

Results Considering DG

In order to find the best place for DG units and their respective optimal sizes in the system, the buses that have minimum fitness values will consider their respective size. The results obtained by using DE method are tabulated and shown in Table 2.

From Table 2, the best three locations with minimum fitness values based on their respective optimal sizes were selected to become candidate buses to install the DG unit in their test system. The associated power losses and voltage levels for each candidate bus are determined using Newton Raphson load flow based on the optimal size of the DG unit. The results are compared in Table 3.

The values of LLC and SCI were increased by an acceptable amount from (0.831) and (0.725) in the normal case to become (0.946) and (1.038) after adding the DG units. Therefore, it is necessary to update the protection devices after including DG units with the distribution system. The voltage levels of test system were increased after including the DG unit within the acceptable limits (0.95-1.1p.u) for generating buses and (0.95-1.05) for load buses (Alsac

The DE method improves the voltage levels of almost all buses while ensuring that no voltage level rises above the acceptable limit. Figure 2 provides a comparison.

Figure 2. Voltage profile comparison

CONCLUSION
Optimal size and suitable location of DG unit that supply only active power (Type 1 DG unit) to the system have been addressed in this paper. The best locations and optimal sizes have been identified by minimising the multi-objective index using artificial intelligence methods. Among the many different heuristic optimisation algorithms, DE provides better results in terms of reduction in real and reactive power losses and improving the voltage profile of the distribution system. Reduction in the real power loss is 21% while reduction in the reactive power losses is 23.96%. The voltage level of bus 14 is increased from 1.019 to 1.0426 after integration with the DG unit.
